

Childhood exposure to non-persistent endocrine disruptors, glucocorticosteroids, and attentional function: A study based on the parametric g-formula

Abstract

Evidence suggests that endocrine disrupting chemicals (EDCs) may perturb the hypothalamic-pituitary-adrenocortical (HPA) axis, which has a major role in brain development. We aimed to evaluate the effects of childhood exposure to organophosphate pesticides, phenols, and phthalate metabolites, on urinary glucocorticosteroids and inattention in children using data from the Human Early-Life Exposome (HELIX) cohort. We used the parametric g-formula to estimate associations between EDCs, glucocorticosteroids, and hit reaction time standard error (HRT-SE), a measure of inattention, and tested for possible effect modification by sex. We observed a positive marginal contrast (MC) for exposure increases from the 10th to the 90th percentile for methyl-paraben (MC: 0.042 and 95% confidence interval (CI): (0.013, 0.071)), and the phthalate metabolites oxo-MiNP (MC: 0.023 and 95% CI: (0.003, 0.044)), oh-MiNP (MC: 0.039 and 95% CI: (0.001, 0.076)), and MEHP (MC: 0.036 and 95% CI: (0.008, 0.063)), on HRT-SE, indicating lower attention. Several EDCs were also associated with a positive MC for cortisone, cortisol, and corticosterone production. Increased levels of the glucocorticosteroids had no effect on HRT-SE, although we found a possible effect modification by sex. Our results suggest that multiple EDCs might interfere with inattention and with the homeostasis of the HPA axis.

The prevalence of several neurodevelopmental disorders has increased in the pediatric population (1), and multiple environmental pollutants may play a role in the increased rates of these disorders (2). Multiple endocrine disrupting chemicals (EDCs), ubiquitous chemicals present in many every-day products and diet, are capable of interfering with the endocrine system, and have shown associations with childhood neurodevelopment and behavior (3–17). Although both pregnancy and early infancy are crucial stages of (neuro)development, most of the available literature is focused on the effects of prenatal exposure to EDCs on child neurodevelopment (2).

One group of EDCs that may have a deleterious effect on neurodevelopment is the organophosphate pesticides (OP pesticides), although the few studies assessing exposure during childhood and through the use of biomarkers suffered from a series of limitations, including a small sample size (2). Exposure to phthalates and their metabolites during childhood and early adolescence has also been associated with several adverse neurodevelopmental outcomes, but these studies were limited to few phthalate metabolites and small study populations (2). The effects of exposure to bisphenol A (BPA) during childhood on cognitive functions are still unclear (2).

Moreover, little is known about the biological mechanisms of action (2). There is some toxicological evidence, however, that exposure to certain EDCs, specifically phthalates, might interfere with the hypothalamic-pituitary-adrenocortical (HPA) axis and might interact with the glucocorticoid receptor (18–20). The HPA axis, which can be activated by stress, is responsible for the production of glucocorticosteroids. The brain, and its proper functioning, is a potential target, due to the presence of receptors for these hormones (19,21). Glucocorticosteroids are necessary for brain maturation, although their under- or over-production might interfere with its normal development and ultimately lead to long-term impaired functioning (20,21).

Taken together, these results suggest that the negative influence of exposure to certain EDCs on neurodevelopmental outcomes might be mediated, at least partially, by disruption of the HPA axis' homeostasis. In the present study, we thus estimated cross-sectional associations between 1) non-persistent EDCs and attentional function, 2) non-persistent EDCs and glucocorticosteroids, and 3) glucocorticosteroids and attentional function, using the parametric g-formula and marginal contrasts (MCs), in children of a large network of cohorts in Europe.

Methods

Study population and design

The Human Early-Life Exposome (HELIX) project aims to characterize early-life exposures and their potential association with endogenous biomarkers and health outcomes (22). It consists of six existing population-based birth cohort studies across Europe: BiB (Born in Bradford, UK) (23), EDEN (Study of determinants of pre- and postnatal developmental, France) (24), INMA (Environment and Childhood, Spain) (25), KANC (Kaunas Cohort, Lithuania) (26), MoBa (The Norwegian Mother and Child Cohort Study, Norway) (27), and

Rhea (Mother–Child Cohort in Crete, Greece) (28). The HELIX subcohort of 1,301 mother-child pairs was fully characterized for the external and internal exposome, including exposure and omics biomarkers during childhood (29). Eligibility criteria for inclusion in the HELIX subcohort included: a) age 6-11 years, with a preference for 7-9 years; b) availability of sufficient stored pregnancy blood and urine samples; c) availability of complete address history from first to last follow-up; d) no serious health problems, which might affect the results of the clinical testing. Ethical permission was obtained from the relevant authorities in the corresponding country.

Variables

Endocrine disrupting chemicals

Children were assessed between December 2013 and February 2016, and assessments included neurological testing and urine collection. Urine samples of the night before and the first morning void on the day of the visit were combined to provide a more reliable exposure assessment. Non-persistent EDCs assessed in the urine samples included phthalate metabolites, phenols, and organophosphate (OP) pesticide metabolites. A list of the environmental chemicals determined in urine samples and used for the present study is given in Table S1. Briefly, we analyzed a total of 7 phenols (bisphenol A (BPA), ethyl-paraben (ETPA), methyl-paraben (MEPA), n-butyl-paraben (BUPA), oxybenzone (OXBE), propyl-paraben (PRPA), triclosan (TRCS)), 6 non-specific organophosphate pesticide metabolites (diethyl dithiophosphate (DEDTP), diethyl phosphate (DEP), diethyl thiophosphate (DETP), dimethyl dithiophosphate (DMDTP), dimethyl phosphate (DMP), dimethyl thiophosphate (DMTP)), and 10 phthalate metabolites (mono benzyl phthalate (MBzP), monoethyl phthalate (MEP), mono-2-ethyl 5-carboxypentyl phthalate (MECPP), mono-2-ethylhexyl phthalate (MEHP), mono-2-ethyl-5-hydroxyhexyl phthalate (MEHHP), mono-2-ethyl-5-oxohexyl phthalate (MEOHP), mono-4-methyl-7-hydroxyoctyl phthalate (oh-MiNP), mono-4-methyl-7-oxooctyl phthalate (oxo-MiNP), mono-iso-butyl phthalate (MiBP), mono-n-butyl phthalate (MnBP)) originating from 6 distinct phthalate parent compounds. The laboratory protocols for the analysis are described elsewhere (30).

Glucocorticosteroids

Urine samples of the night before the day of the visit were used to measure levels of the glucocorticosteroids. These included glucocorticosteroids, glucocorticosteroid metabolites, glucocorticosteroid precursors, glucocorticosteroid precursor metabolites, androgens, and androgen metabolites. A list of the glucocorticosteroids determined in urine samples and used for the present study is given in Table S2.

To assess the levels of glucocorticosteroids and their metabolites, LC-MS/MS analysis was applied at the Applied Metabolomics Research Group, IMIM (Hospital del Mar Medical Research Institute). The laboratory protocols for the analysis are described elsewhere (31,32).

Three additional markers, total cortisol production, total cortisone production, and total corticosterone production, were computed based on the following: cortisol production as the sum of cortisol and its metabolites (20 α -dihydrocortisol (20aDHF), 20 β -dihydrocortisol

(20bDHF), 5 α ,20 α -cortol (5a20acortol), 5 α ,20 β -cortol (5a20bcortol), 5 α -tetrahydrocortisol (5aTHF), 5 β ,20 α -cortol (5b20acortol), 5 β ,20 β -cortol (5b20bcortol), 5 β -dihydrocortisol (5bDHF), 5 β -tetrahydrocortisol (5bTHF), 6 β -hydroxycortisol (6OHF)), cortisone production as the sum of cortisone and its metabolites (20 α -dihydrocortisone (20aDHE), 20 β -dihydrocortisone (20bDHE), 5 α -tetrahydrocortisone (5aTHE), 5 β ,20 α -cortolone (5b20acortolone), 5 β ,20 β -cortolone (5b20bcortolone), 5 β -tetrahydrocortisone (5bTHE), 6 β -hydroxycortisone (6OHE)), and corticosterone production as the sum of 11-dehydrocorticosterone (A), 17-deoxycortolone (17-DO-cortolone), 5 α -tetrahydrocorticosterone (5aTHB), 5 β -tetrahydrocorticosterone (5bTHB).

Attentional function

Cognitive and motor function outcomes were assessed with standardized, non-linguistic, and culturally blind computer tests, including the Attention Network Test (ANT) (33), which provides a measure of efficiency of attentional function. The tests were administered in a standardized way, and with minimal interference from the field workers. Further information can be found in (29). The outcome of interest for the present study is the hit reaction time standard error (HRT-SE) (34), a measure of response speed consistency throughout the test. A high HRT-SE indicates highly variable reaction times, and is considered a measure of inattentiveness.

Confounders

For each research question, defined by a specific type of exposure and outcome, the minimal set of covariates for inclusion in the analyses was selected on the basis of a directed acyclic graph (DAG) built with DAGitty (35) and ggdag (36). The sets of covariates were selected to estimate the total effect of the exposure on the outcome. For effect estimation of the EDCs on glucocorticosteroids and of glucocorticosteroids on HRT-SE, these sets were also sufficient to estimate direct effects. Sample-specific creatinine values were used to adjust for possible dilution effects. Further, each minimal adjustment set was *augmented* with precision covariates, defined as the set of parents variable of the outcome that are not parents of the exposure. Common confounders were cohort, ethnicity, sex, age, height, weight, and head circumference of the child, consumption of fish, fruit, vegetables, organic food, and fast food, maternal tobacco consumption, family financial situation and affluence scale (FAS). Models for estimating the effects of EDCs on HRT-SE were further adjusted for child breastfeeding, prenatal maternal active and passive smoking, urine creatinine, child mood and rest before assessment, child neuropsychological diagnosis, marital status, season, and fasting time before assessment. Models for estimating the effects of EDCs on glucocorticosteroids were further adjusted for urine creatinine, season, and fasting time before assessment. Models for estimating the effects of glucocorticosteroids on HRT-SE were further adjusted for child breastfeeding, prenatal maternal active and passive smoking, marital status, EDCs, urine creatinine, child mood and rest before assessment, and child neuropsychological diagnosis. The adjustment sets are provided in the Supplementary Material as text files compatible with DAGitty. Codebooks for the used covariates, by research question, are provided in Supplementary Tables 3, 4, 5.

Statistical methods

Data pre-processing

Concentrations of the glucocorticosteroids were classified as quantifiable, below the limit of quantification (LOQ), possible interference or out of range, and not detected. For each metabolite, we computed the fraction of values below the LOQ and not detected, both within each cohort and overall. We proceeded to impute these values using half the value of the corresponding LOQ, for those metabolites that had less than 30% of missings within each cohort and 20% of missings overall. Information about the lower limit of quantification (LLOQ) for the glucocorticosteroids is provided in [Table S6](#). The remaining missing values were imputed using kNN from the `VIM` R package ([37](#)), for those metabolites that had less than 40% of remaining missings within each cohort and 30% of remaining missings overall. We used 5 nearest neighbors. We natural log-transformed them to improve model fit, assessed with posterior predictive checks. To do so, replicated data were simulated with the fitted models and compared to the observed data. We used the `check_predictions` function from the `performance` R package using the default arguments ([38](#)). Values of total cortisol, cortisone, and corticosterone production were expressed in nanograms per millilitre (ng/ml).

Concentrations of the non-persistent EDCs were classified as quantifiable, below the limit of detection (LOD), possible interference or out of range, and not analysed. Concentrations below the LOD were singly imputed using a quantile regression approach for the imputation of left-censored missing data, as implemented in the `impute.QRILC` function from the `imputeLCMD` R package ([39](#)). Information about the lower limits of detection can be found in ([30](#)). Chemicals with more than 70% of observations below the LOD were excluded from the present study. Remaining missing values were imputed similarly using kNN. Values of the chemicals were expressed in μ grams per litre (μ g/L).

Missing values in the clinical outcome were imputed similarly using kNN. We natural log-transformed these to improve model fit, assessed with posterior predictive checks. Values of the clinical outcome were expressed in milliseconds (ms).

Missing values in the covariates were imputed similarly using kNN. Categorical covariates were imputed using the `maxCat` function, which chooses the level with the most occurrences. Creatinine values were expressed in grams per litre (g/L).

Estimation of balancing weights

To reduce the effect of measured confounders on the exposure-outcome association, stabilized balancing weights were estimated using the energy method available in the `weightIt` R package ([40](#)). This method estimates weights by minimizing an energy statistic related to covariate balance ([41](#)), thus avoiding the need to specify a parametric model. Weights below the 0.1 and above the 0.9 quantiles were trimmed. Trimming might lead to decreased covariate balance and potentially change the estimand, but can also decrease the variability of the weights. Covariate balance was assessed using functionalities provided by the `cobaIt` R package ([42](#)). Specifically, we used *Love* plots to visualize covariate balance before and after adjusting.

186 G-computation

187 We estimated MCs with the parametric g-formula, a method of standardization. The
188 parametric g-formula involves the following steps: 1) fit a outcome model including both
189 covariates and balancing weights; 2) create two new datasets identical to the original one
190 but with the exposure shifted according to a user-specified intervention set by a
191 deterministic function of the observed exposure levels; 3) use the outcome model to
192 compute adjusted predictions in the two counterfactual datasets; 4) compute the difference
193 between the means of the adjusted predictions in the counterfactual datasets. The causal
194 parameter of interest was thus specified as the difference in the expected counterfactual
195 outcomes under the shifted exposure levels ($E[Y^{d_1}] - E[Y^{d_2}]$). In order for this parameter
196 to be identified, the usual causal identifiability conditions (no unmeasured confounding,
197 positivity, and consistency) are required. Since these conditions are likely not satisfied, we
198 focused on the estimation of a statistical estimand that is as close as possible to the causal
199 parameter of interest.

200 We fit the outcome model using the `glm` function and a Gaussian family with identity link
201 from base R. The exposure variable was modeled using natural cubic splines with 3 degrees
202 of freedom, to more flexibly capture the average dose-response function (ADRF).

203 To estimate the MCs, we used the `avg_comparisons` function from the `marginaleffects` R
204 package (43). The two counterfactual datasets were obtained by setting the exposures
205 levels to 90th percentile (d_1) and the 10th percentile (d_2), for each cohort separately. The
206 MCs were computed using the estimated balancing weights above. Robust standard errors
207 were computed with the `sandwich` R package, using cohort as variable indicating clustering
208 of observations (44,45). For each outcome, we report the results as differences between
209 MCs.

210 The R code to reproduce analyses and results is available online
211 (<https://github.com/lorenzoFabbri/paper-helixSC-neuro>).

212 Effect-modification analysis

213 We further estimated separate MCs for possible effect-modification by sex. To do so,
214 balancing weights were estimated separately for each level of the sex variable, and an
215 interaction term between the exposure and sex was included in the outcome model.
216 Similarly, the MCs were aggregated separately for each level of sex.

217 Results

218 Table 1 and Table S7 provide descriptive statistics for the outcome and covariates for the
219 HELIX subcohort and for each cohort, respectively. Of the 1,301 children of the HELIX
220 subcohort, 1,297 had measurements of the non-persistent EDCs. Measurements of the
221 glucocorticosteroids were available for 1,004 children, of which 980 were matched to the
222 HELIX subcohort. Measurements of both non-persistent EDCs and glucocorticosteroids
223 were available for 976 children of the subcohort. A flowchart describing the sample size for

each research question is presented in [Figure S1](#). The sample consisted of 55% males. The median HRT-SE was 300 ms (interquartile range (IQR), 231-368), with lower median values for EDEN, MOBA, and INMA, corresponding to the cohorts with older children. At the time of visit, the median age of the children was 8.06 years. The children were mostly Caucasian (90%), and the largest minority were of Pakistani origin (6.2%).

Levels of unprocessed non-persistent EDCs, after imputation of values below the LOD, and glucocorticosteroids, are presented in [Table 2](#), [Table 3](#), and [Table S8](#). Supplementary Figures 2 and 3 provide information on the measurement classification of the EDCs and glucocorticosteroids by cohort, respectively.

The effective sample sizes before and after balancing weights estimation are presented in Supplementary Tables 9, 10, 11, while basic summary statistics of the estimated balancing weights are presented in Supplementary Tables 12, 13, 14. As expected, the median value of the weights for each exposure was close to 1.00.

[Figure 1](#) presents the forest plot for the MCs on the logarithmic scale of the non-persistent EDCs on HRT-SE. For most EDCs, a cohort-specific increase in the levels of the exposures from the 10th to the 90th percentiles was associated with a positive MC, indicating an increase in the values of HRT-SE and thus lower attention. Most of the confidence intervals (CIs) included the null effect, though. Significant effects were observed for the paraben MEPA (MC: 0.042 and 95% CI: (0.013, 0.071)), and the phthalate metabolites oxo-MiNP (MC: 0.023 and 95% CI: (0.003, 0.044)), oh-MiNP (MC: 0.039 and 95% CI: (0.001, 0.076)), and MEHP (MC: 0.036 and 95% CI: (0.008, 0.063)). The organophosphate pesticide (OP pesticide) DETP was negatively associated with HRT-SE (MC: -0.026 and 95% CI: (-0.054, 0.001)).

[Figure 2](#) presents the forest plot for the MCs on the logarithmic scale of the non-persistent EDCs on total cortisone, cortisol, and corticosterone production. For most EDCs, a cohort-specific increase in the levels of the exposures from the 10th to the 90th percentiles was associated with a positive MC, indicating an increase in the total production of these metabolites. Exceptions were BUPA, which was associated with negative MCs for all three outcomes, and MiBP, which was associated with a negative MC for total cortisone production only. The majority of the effects for the phenols and phthalate metabolites included the null. The phenol BPA showed the largest MCs across all three outcomes (cortisone production, MC: 0.263 and 95% CI: (0.131, 0.394); cortisol production, MC: 0.274 and 95% CI: (0.107, 0.441); corticosterone production, MC: 0.285 and 95% CI: (0.106, 0.464)).

[Figure 3](#) presents the forest plot for the MCs on the logarithmic scale of the glucocorticosteroids on HRT-SE. All MCs included the null, with no clear indication of directionality of the effect.

Effect modification by sex

Basic summary statistics of the estimated balancing weights for effect modification are presented in Supplementary Tables 15, 16, 17. As expected, the median value of the weights for each exposure was close to 1.00.

Table 4 presents the results of the difference between estimates of the MCs on the logarithmic scale for females and males, for the EDCs on the glucocorticosteroids and HRT-SE. For HRT-SE, significant differences were present for the phenol OXBE (MC: 0.032 and 95% CI: (0.004, 0.061)) and the phthalate metabolite MbZP (MC: -0.066 and 95% CI: (-0.126, -0.007)). For the glucocorticosteroids, significant differences were present across all three classes of EDCs and for all outcomes. The largest differences were attributable to the phenol ETPA (corticosterone production, MC: -0.254 and 95% CI: (-0.416, -0.092)) and the phthalate metabolite MEHP (cortisol production, (MC: -0.221 and 95% CI: (-0.289, -0.153)); cortisone production, (MC: -0.177 and 95% CI: (-0.299, -0.055))). The forest plots of the individual MCs are presented in Supplementary Figures 4 and 5.

Table 5 presents the results of the difference between estimates of the MCs on the logarithmic scale for females and males, for the glucocorticosteroids on HRT-SE. Significant differences were present for cortisone production (MC: 0.14 and 95% CI: (0.019, 0.261)) and corticosterone production (MC: 0.126 and 95% CI: (0.009, 0.243)). Furthermore, for all exposures, the MCs had opposite sign (positive for males and negative for females). The forest plot of the individual MCs is presented in Figure S6.

Discussion

In this study, consisting of 1,297 children from 6 European birth cohorts, we observed that short-term childhood exposure to certain non-persistent EDCs was associated with attentional function (MEPA, MEHP, oh-MiNP, and oxo-MiNP), and with total production of cortisol, cortisone, and corticosterone (DEP, DMP, DMTP, BPA, ETPA, MEPA, MEHP, oh-MiNP, and oxo-MiNP). Increased production of these glucocorticosteroids did not seem to affect attentional function. Some of these associations differed for females and males.

To the best of our knowledge, no other study has investigated the effects of childhood exposure to multiple classes of non-persistent EDCs in relation to attentional function. More generally, the literature on childhood exposure to non-persistent EDCs and other neurodevelopment outcomes in children has mostly focused on OP pesticides (3,4,6,8), phthalate metabolites (5,9,10,15,17,46–48), and BPA (7,13,14).

In children aged 6 to 11 years, higher levels of dialkylphosphate (DAP) metabolites were associated with lower scores of intelligence quotient (IQ) and verbal comprehension, especially in boys (4), while higher levels of diethylphosphate metabolites were associated with lower working memory scores (6). There is also preliminary evidence of a possible association between exposure to certain OP pesticides and Attention-Deficit / Hyperactivity Disorder (ADHD) in children (3,8).

Preliminary evidence is also available for several phthalate metabolites in relation to cognitive development in childhood. Higher levels of di(2-ethylhexyl) phthalate metabolites (including MEHP, MEHHP, and MEOHP) were associated with lower intelligence scores in children aged 2 to 12 years (5), lower scores of IQ and verbal intelligence, more omission errors (a measure of inattention), and higher scores of response time variability (a measure of sustained attention) in 6-year old Korean children

(10), poorer fine motor skills in preadolescent boys (47), and lower intelligence scores in 7-year old children (17). Further associations were found for MEOHP with lower scores of IQ (5) and verbal intelligence in Taiwanese children aged 6 to 12 years (9), and for dibutyl phthalate metabolites (MnBP and MiBP) with impaired verbal intelligence (9). Few studies have looked into different classes of non-persistent EDCs. Shoaff et al. investigated cross-sectional associations between multiple EDCs and ADHD-related behaviors in 15-year old adolescents, finding a higher risk of ADHD-related behavior problems with higher levels of antiandrogenic phthalate metabolites, especially in boys (15). Our findings, indicating that short-term childhood exposure to certain phthalate metabolites (MEHP, oh-MiNP, and oxo-MiNP) was associated with attentional function, adds to this growing evidence base suggesting that childhood phthalate exposure may impact child neurodevelopment.

Among phenols, some studies provide preliminary evidence of an association between BPA and ADHD in children aged 8 to 15 years (7) and in a case-control study of children aged 6 to 12 years (13), especially in boys. Except for working memory, there was no evidence of an association between BPA and cognitive abilities in Spanish boys aged 9 to 11 years (14). We did not observe an association between BPA and attention function in the present study, but this study is the first to suggest that childhood paraben (MEPA) exposure may be associated with attentional function.

We are not aware of other epidemiological studies investigating childhood exposure to phthalates metabolites, phenols, and OP pesticides, in relation to urinary glucocorticosteroid levels in childhood. However, prior epidemiological research provides preliminary evidence for an association between certain non-persistent EDCs measured at other time points with higher levels of glucocorticoids measured in other biological matrices (18–20). Repeated measures up to 15 months of age of the phthalate metabolites MEHHP, MEOHP, MiBP, and MnBP showed positive associations with free cortisol in urine in Korean children (18). In a cohort of Chinese pregnant women, phthalate metabolites were measured at 14, 24, and 36 weeks of gestation, and the glucocorticoids cortisol and cortisone were measured in cord blood. Third-trimester levels of MEHP were positively associated with cortisol, while MECPP and MEOHP were negatively associated with cortisone (19). Time- and chemical-dependent sex differences were also found: during the third trimester, MEHHP and MEOHP were positively associated with cortisol in females, while negatively associated in males (19). In a longitudinal study, a mixture of several phthalate metabolites, driven by MEP, MiBP, and MBzP, measured in childhood, showed a positive association with hair cortisol measured at 12 years of age (20). Our findings also indicate associations between certain phthalate metabolites (MEHP, oh-MiNP, and oxo-MiNP) and glucocorticosteroids, but differences in the exposure assessment time points and in the biological matrices used for glucocorticosteroids determinations make a direct comparison difficult.

Adding to these epidemiological studies, previous toxicological research provide evidence for the inhibition by phthalates of human 11 β -hydroxysteroid dehydrogenase 2 (11 β -HSD2) activity, responsible for the conversion of active cortisol into inactive cortisone (49,50). There is also *in silico* evidence suggesting that BPA, a phenol, and Triazophos (TAP), a organophosphorus insecticide, can bind to the human glucocorticoid receptor (51,52).

We are also not aware of prior epidemiological studies specifically investigating the effects of elevated levels of glucocorticosteroids in relation to attentional function, although there is evidence that under- or over-production of glucocorticosteroids interfere with the normal development of the brain (21).

Our findings should be interpreted in light of the following strengths and limitations. Strengths include its relative large sample size and its inclusion of multiple classes of non-persistent EDCs. Further, this study used pooled urine samples for chemical assessment to obtain more representative long-term exposures, since it is known that these specific EDCs have very short half-lives (53,54). We decided to model both the *treatment* mechanisms, for the estimation of balancing weights, and the outcomes, with traditional covariates adjustment, to try to obtain *doubly robust* effect estimates. Finally, we decided not to interpret our results by focusing on the estimated coefficients of possibly misspecified regression models, but by making use of the g-computation procedure.

Limitations include the cross-sectional design of the present study. Importantly, the non-persistent EDCs were measured in a pool of night and morning urine samples before the clinical visit, to represent exposure over the previous day, whereas the glucocorticosteroids were measured in the night urine sample. Although we included a wide range of confounders there is the possibility, as with other observational studies, of residual confounding, which might lead to a bias away from the null. There is further the possibility of misspecification of the outcome model, although we included a spline of the exposure to relax some of the linearity assumptions.

In conclusion, in a study of 1,297 children from 6 European birth cohorts, we observed that (i) exposure to non-persistent EDCs might have short-term effects on HRT-SE, (ii) exposure to non-persistent EDCs might disrupt the HPA axis, and (iii) disruption of the HPA axis might have short-term, sex-specific effects on HRT-SE.

600 **Study populations**

Table 1: Participant characteristics (HELIX subcohort; 2013-2016).

Characteristic	N = 1,297 ^a
Child age (years)	8.1 (6.5, 8.9)
Child breastfeeding	1,093.0 (84.7%)
Unknown	6
Child ethnicity	
Caucasian	1,157.0 (90.0%)
Pakistani	80.0 (6.2%)
Asian	21.0 (1.6%)
Other	19.0 (1.5%)
African	7.0 (0.5%)
Native American	2.0 (0.2%)
White non European	0.0 (0.0%)
Unknown	11
Child head circumference (cm)	51.8 (50.6, 52.9)
Unknown	3
Child height (m)	1.3 (1.2, 1.4)
Child neuropsychological diagnosis	95.0 (7.3%)
Child rest before assessment	
Yes	1,209.0 (93.3%)
Not as well as usual	87.0 (6.7%)
Unknown	1
Child sex	
Male	710.0 (54.7%)
Female	587.0 (45.3%)
Child weight (kg)	26.9 (22.9, 32.6)
Child mood before assessment	
Usual	1,232.0 (95.1%)
Not usual	64.0 (4.9%)
Unknown	1
Cohort	
MOBA	272.0 (21.0%)
INMA	221.0 (17.0%)
BIB	204.0 (15.7%)
KANC	203.0 (15.7%)
RHEA	199.0 (15.3%)
EDEN	198.0 (15.3%)
Creatinine night sample (g/l)	1.7 (0.9, 3.0)
Unknown	321
Creatinine pooled sample (g/l)	1.0 (0.8, 1.2)

Date of test (season)	
Spring	358.0 (27.7%)
Winter	339.0 (26.2%)
Autumn	300.0 (23.2%)
Summer	297.0 (23.0%)
Unknown	3
Family affluence scale	
6	410.0 (31.7%)
5	325.0 (25.1%)
7	248.0 (19.2%)
4	174.0 (13.4%)
3	92.0 (7.1%)
2	28.0 (2.2%)
1	12.0 (0.9%)
0	6.0 (0.5%)
Unknown	2
Fast food/take away (times/week)	0.1 (0.1, 0.5)
Unknown	7
Fasting time before visit (hours)	3.3 (2.8, 4.0)
Financial situation of the parents	
Doing alright	414.0 (32.1%)
Living comfortably	412.0 (31.9%)
Getting by	331.0 (25.6%)
Finding it quite difficult	86.0 (6.7%)
Finding it very difficult	40.0 (3.1%)
Does not wish to answer	8.0 (0.6%)
Unknown	6
Fish and seafood (times/week)	2.0 (1.1, 3.5)
Unknown	5
Fruits (times/week)	9.0 (5.9, 18.0)
Unknown	7
Hit reaction time standard error (ms)	299.6 (231.3, 368.2)
Unknown	18
Marital status	
Living with the father	1,212.0 (94.5%)
Living alone	39.0 (3.0%)
Other situation	31.0 (2.4%)
Unknown	15
Maternal tobacco consumption	

Non-smoker and has never smoked	681.0 (52.6%)
Daily smoker	200.0 (15.5%)
Non-smoker but previously smoked daily	186.0 (14.4%)
Non-smoker but previously smoked although not daily	163.0 (12.6%)
Smoker but not daily	64.0 (4.9%)
Unknown	3
Organic food (times/week)	0.5 (0.0, 3.0)
Unknown	7
Pregnancy maternal active smoking	190.0 (15.1%)
Unknown	40
Pregnancy maternal passive smoking	514.0 (40.3%)
Unknown	21
Vegetables (times/week)	6.5 (4.0, 10.0)
Unknown	6

^aEstimate and 95% CI.

Table 5: Pairwise differences between marginal contrasts on the logarithmic scale of males and females, for the effect of a increase from the 10th to the 90th percentile of the glucocorticosteroids on hit reaction time standard error (HRT-SE) expressed in ms

(HELIX subcohort; 2013-2016).

	HRT-SE ^a
Glucocorticosteroids	
corticosterone production	0.126 (0.009, 0.243)
cortisol production	0.096 (-0.045, 0.238)
cortisone production	0.14 (0.019, 0.261)

^aEstimate and 95% CI.

607 **Figures for main results**

608 **Marginal contrasts**

Figure 1: Marginal contrasts on the logarithmic scale for the effect of a increase from the 10th to the 90th percentile of the endocrine disrupting chemicals (EDCs) on hit reaction time standard error (HRT-SE) expressed in ms (HELIX subcohort; 2013-2016). Circles indicate effect estimates. Solid lines indicate the 95 % CI. The size of the circles represents the S value of the effect estimate (55).

Figure 2: Marginal contrasts on the logarithmic scale for the effect of a increase from the 10th to the 90th percentile of the endocrine disrupting chemicals (EDCs) on the glucocorticosteroids expressed in ng/ml (HELIX subcohort; 2013-2016). Circles, triangles, and squares indicate effect estimates. Solid lines indicate the 95 % CI. The size of the circles represents the S value of the effect estimate (55).

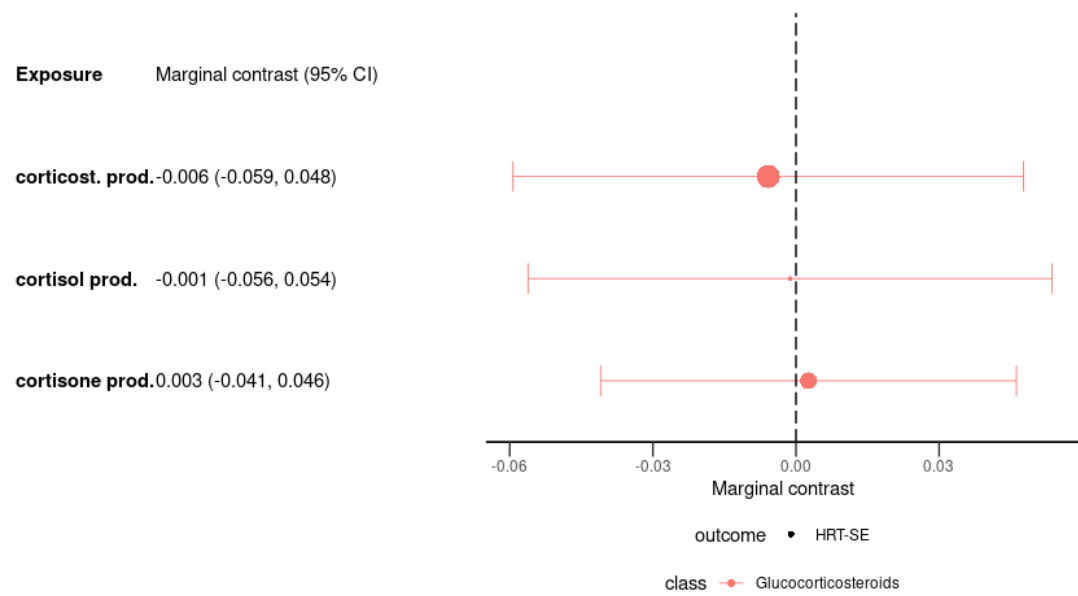

Figure 3: Marginal contrasts on the logarithmic scale for the effect of a increase from the 10th to the 90th percentile of the glucocorticosteroids on hit reaction time standard error (HRT-SE) expressed in ms (HELIX subcohort; 2013-2016). Circles indicate effect estimates. Solid lines indicate the 95 % CI. The size of the circles represents the S value of the effect estimate (55). Abbreviations: cortisone production (cortisone prod.); cortisol production (cortisol prod.); corticost. prod. (corticosterone production).
